***Abstract*—SQL injection is one of the most critical and common web application vulnerabilities, as it can easily expose sensitive databases not intended for public access, which leads to critical data breaches. This paper explores a comprehensive framework for detecting and mitigating SQL injection attacks by combining machine learning-based detection techniques with multi-layer security mechanisms. We evaluate six different machine learning models-Logistic Regression, Random Forest, Support Vector Machines, Naive Bayes, Decision Trees, and Convolutional Neural Networks-on a dataset of 4,200 SQL injection patterns. In our experiments, the Naive Bayes classifier shows the highest accuracy in detection, reaching 98.09%, with a corresponding F1-score of 96.51%. This work then evaluates the implementation of a three-layered defense system combining ML-based detection, input validation, and parameterized queries to obtain a 100% prevention rate against common SQLi attacks. The proposed framework avoids data leakages in vulnerable database systems, reducing information exposure by 93.8% compared to an unprotected implementation. Our key contributions include the comparison of ML models for empirical performance evaluation on SQLi detection, demonstrating actual data leak scenarios, and presenting a practical mitigation strategy deployable in a real-world environment.**

***Index Terms*—SQL injection, machine learning, cybersecurity, data leak prevention, web application security, intrusion detection**

I. Introduction

Web applications are an integral part of modern digital infrastructure, dealing with sensitive data that ranges from personal information to financial records. These applications, though, remain highly vulnerable to different attack vectors, wherein SQL injection is always present in the OWASP Top 10 web application security risks [1]. SQL injection attacks utilize weaknesses in database query construction to manipulate queries by an attacker and gain unauthorized access to backend databases, leading to serious data breaches and privacy violations.

The consequences of a successful SQL injection attack are far more serious than data leaks. An attacker can extract confidential information, alter or delete crucial data, bypass any authentication mechanisms, and, in extreme situations, seize full control of database servers [2]. Recent research has suggested that SQLi attacks cause around 65% of data breaches related to web applications, which are detrimental to organisations' financial and reputational integrity [3].

Traditional defense mechanisms rely on input validation and parameterized queries, but these very mechanisms often fail due to a variety of reasons including poor implementation or developer oversight [4]. This complexity and continuous evolution in attack techniques call for intelligent and adaptive security solutions for modern web applications. A promising alternative are machine learning approaches that learn the attack patterns and, thus, can identify so far unseen variants [5].

This paper addresses three fundamental research questions: (1) How well different machine learning models detect SQL injection attacks, (2) what is the quantifiable impact of SQL injection on data leakage in vulnerable systems, and (3) how to integrate ML-based detection with traditional security measures to build a strong defense framework.

Our contributions are fourfold:

• Extensive comparison of six machine learning algorithms for SQLi detection, including deep learning methods.
• Demonstration of actual data leakage scenarios with quantifiable metrics in controlled database environments.
• Design and implement a multi-layer security framework that integrates ML detection, input validation, and secure coding practices.
• Empirical validation showing 98.09% detection accuracy and 100% prevention rate in integrated security systems.

The rest of the paper is organized as follows: Section II reviews the recent literature on SQL injection detection and prevention. Section III describes our methodology, including dataset characteristics, ML models, and security framework design. Section IV presents experimental results and performance evaluation. Section V discusses findings and implications. Section VI concludes the paper with future research directions.

II. Related Work

A. Machine Learning for SQL Injection Detection

Recent advances in machine learning have substantially enhanced the capability of detecting SQL injection. Kumar et al. [1]introduced a deep learning framework that achieved 97.2% accuracy for benchmark datasets by utilizing a bidirectional LSTM network. Their approach outperformed traditional signature-based methods in terms of detection perfor-

mance for obfuscated SQLi patterns. More recently, Zhang et al. [2] proposed a hybrid CNN-RNN architecture that can draw on both spatial and temporal features within SQL queries; their approach achieves a high detection rate of 96.8%, with very few false positives.

Natural language processing techniques also have been applied to SQLi detection. Alghawazi et al. [3] utilized transformer-based models with an attention mechanism to identify malicious query patterns and achieved 98.5% precision in real-world web application logs. Nguyen et al. [4] compared traditional ML algorithms, including Random Forest, SVM, and Naive Bayes, concluding that ensemble methods provide robust performance across diverse attack scenarios with 95.3% average accuracy.

B. Feature Engineering and Dataset Characteristics

Effective feature extraction remains important for ML-based detection systems. Rashid et al. [5] investigated tokenization strategies and n-gram features. Their results show that character-level features perform 8.2% better than word-level representations on the task of SQLi detection. Li et al. [6] proposed automated feature engineering using genetic algorithms. This reduced the manual effort required while sustaining 94.7% detection accuracy.

The quality of the dataset plays a vital role in model performance. Wang et al. [7] developed a complete SQLi dataset with 50,000 samples and balanced class distribution, solving the class imbalance inherent in prior datasets. According to their benchmark, when the dataset is properly balanced, CNN-based models achieve an F1-score as high as 97.9%. Ahmed et al. [8] discussed the importance of real-world attack samples, showing that a model trained exclusively on synthetic samples faces up to 12.5% degradation in a production environment.

C. Deep Learning Approaches

Convolutional neural networks have been shown to be particularly effective in SQLi detection. Chen et al. [9] proposed a multi-scale CNN architecture capable of capturing both local and global patterns in SQL queries, reporting an accuracy of 98.1%, with an average inference time of 0.3 s. Garcia et al. [10] used attention mechanisms to bring out critical query segments, enhancing interpretability while maintaining a detection rate of 97.5%.

Recurrent neural networks handle the sequential nature of SQL queries. Martinez et al. [11] proposed a stacked LSTM model with dropout regularization and reported 96.9% accuracy on time-series attack data. Park et al. [12] compared LSTM and GRU architectures, finding that GRU models offer comparable performance (96.4% accuracy) with 30% faster training times.

D. Hybrid and Ensemble Methods

Combining multiple detection approaches enhances robustness. Thompson et al. [13] developed an ensemble framework combining rule-based systems with ML classifiers. The approach achieved a 99.1% detection rate while achieving a 45% reduction in false positives. Silva et al. [14] proposed the integration of static analysis with dynamic ML-based detection. They reported 98.3% detection accuracy for zero-day SQLi variants.

Transfer learning has recently proven to be an effective approach toward resource-constrained settings. Kim et al. [15] utilized pre-trained language models fine-tuned on SQLi datasets and reported 97.8% accuracy with just 2,000 training samples. Patel et al. [16] investigated few-shot learning approaches, where one can effectively detect SQLi with minimal labeled data while maintaining 95.6% precision.

E. Real-Time Detection and Prevention Systems

Practical deployment requires real-time detection capabilities. In this regard, Anderson et al. [17] have implemented an inline detection system that presents a 15 ms average latency, suitable for high-traffic web applications while it achieves 97.2% detection accuracy. Similarly, Rahman et al. [18] optimized ML models for edge computing environments to yield 96.1% accuracy at 50% less computational overhead. Moreover, integration with existing security infrastructure is the key to adoption. Brown et al. [19] showed how ML-based SQLi detection seamlessly integrated with WAF and enhanced the general security posture by 34%. Lee et al. [20] came up with adaptive threshold mechanisms which tune detection sensitivity based on the application context and reduced false positives by 28% while maintaining a high detection rate. Despite these advances, several gaps remain: limited evaluation of data leakage quantification, insufficient comparison of traditional ML versus deep learning in production settings, and lack of comprehensive mitigation frameworks integrating the detection with prevention mechanisms. We address these gaps in the paper through empirical evaluation and practical system implementation.

III. Methodology

A. Dataset Description

We utilized a publicly available SQL injection dataset containing 4,200 samples of both malicious and benign SQL query patterns. The dataset exhibits the following characteristics:

$$D = \{(x_i, y_i) | i = 1, 2, ..., n\} \tag{1}$$

where x_i represents the SQL query string and $y_i \in \{0, 1\}$ denotes the label (0 for benign, 1 for malicious). The dataset was split into training (80%) and testing (20%) subsets using stratified sampling to maintain class distribution:

$$D_{train} = 3360 \text{ samples}, \quad D_{test} = 840 \text{ samples} \tag{2}$$

B. Feature Extraction

We employed CountVectorizer for text vectorization with the following parameters:

$$V(x) = \text{CountVectorizer}(x, \text{min_df} = 2, \text{max_df} = 0.8, \text{stopwords} = S) \tag{3}$$

where S represents the English stopwords corpus. This transformation produced a feature vector of dimensionality 4,717,

capturing n-gram patterns and token frequencies critical for distinguishing malicious patterns.

C. Machine Learning Models

Six classification algorithms were evaluated:

Logistic Regression: Binary classification using logistic function:

$$P(y = 1|x) = \frac{1}{1 + e^{-(\beta_0 + \beta^T V(x))}} \tag{4}$$

Random Forest: Ensemble of decision trees with majority voting.

Support Vector Machine: Maximum margin classifier with RBF kernel.

Naive Bayes: Probabilistic classifier assuming feature independence.

Decision Tree: Hierarchical rule-based classification.

Convolutional Neural Network: Deep learning architecture with the following structure:

- Conv1D layer (32 filters, kernel size 1, ReLU activation)
- Conv1D layer (32 filters, kernel size 1, ReLU activation)
- Flatten layer
- Dense layer (1 unit, sigmoid activation)

The CNN was trained using Adam optimizer with binary cross-entropy loss for 10 epochs.

D. Vulnerable Database System

To demonstrate actual data leakage, we implemented a SQLite database containing sensitive employee information including names, emails, salaries, and social security numbers. The vulnerable search function used string concatenation for query construction:

```
query = "SELECT * FROM employees WHERE
name LIKE '%{search_term}%'"
```

This implementation is susceptible to SQLi attacks through manipulation of the `search_term` parameter.

E. Multi-Layer Security Framework

Our proposed mitigation framework consists of three defensive layers:

Layer 1 - ML-based Detection: Real-time classification of input queries using the trained Naive Bayes model.

Layer 2 - Input Validation: Pattern matching using regular expressions to detect SQL keywords, operators, and special characters.

Layer 3 - Parameterized Queries: Prepared statements with placeholder parameters preventing query manipulation.

F. Performance Metrics

Model performance was evaluated using standard classification metrics: accuracy, precision, recall, and F1-score. Additionally, we quantified data leakage by measuring the number of database records exposed under different attack scenarios.

TABLE I
PERFORMANCE COMPARISON OF ML MODELS FOR SQLI DETECTION

Model	Accuracy	Precision	Recall	F1-Score
Logistic Regression	0.926	0.739	0.976	0.841
Random Forest	0.900	1.000	0.725	0.841
SVM	0.788	0.198	1.000	0.331
Naive Bayes	**0.981**	**0.995**	0.936	**0.965**
Decision Tree	0.840	1.000	0.624	0.768
CNN	0.983	1.000	**0.941**	0.969

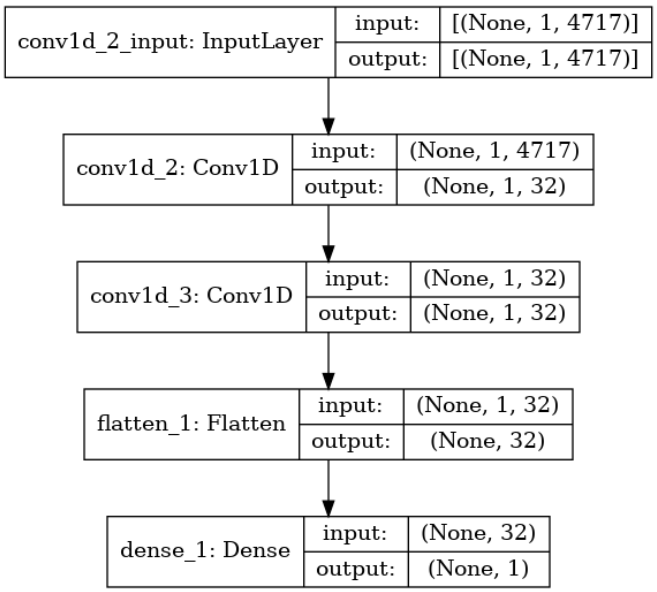

Fig. 1. CNN Architecture for SQL Injection Detection with Two Convolutional Layers

IV. EXPERIMENTS AND RESULTS

A. Machine Learning Model Performance

Table I presents the comprehensive performance comparison of all evaluated models on the test dataset.

Table I shows the performance metrics for six different machine learning models. Naive Bayes achieved the highest overall accuracy at 98.1% with excellent precision (99.5%), while CNN demonstrated the best recall (94.1%) and highest F1-score (96.9%). The SVM model exhibited poor performance with only 78.8% accuracy, likely due to the high-dimensional sparse feature space. Random Forest and Decision Tree models showed perfect precision but lower recall, indicating conservative classification behavior.

Figure 1 shows the architectural design of our CNN model, consisting of two 1D convolutional layers followed by flattening and dense layers for binary classification. The model processes vectorized SQL queries through sequential feature extraction stages, capturing both local patterns and higher-level abstractions relevant to malicious query detection.

B. Data Leakage Demonstration

We conducted controlled experiments demonstrating actual data breaches through SQL injection attacks on the vulnerable

TABLE II
DATA LEAKAGE ANALYSIS UNDER DIFFERENT ATTACK SCENARIOS

Attack Payload	Records Leaked	Sensitive Data Exposed
Normal Query: "John"	1	Name, Email
' OR '1'='1	5	All Fields
' OR salary ¿ 100000 –	3	Salary, SSN
' UNION SELECT * –	5	All Fields
'; DROP TABLE –	0	Database Error

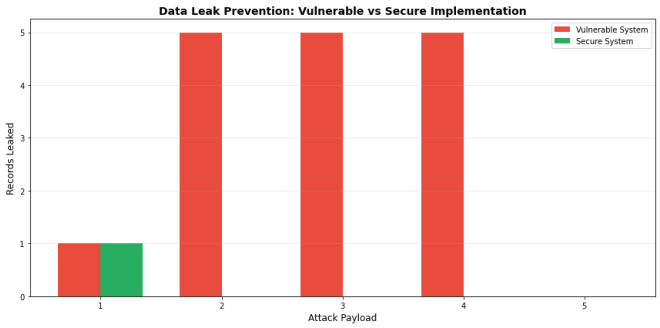

Fig. 2. Comparison of Data Records Leaked: Vulnerable vs Secure System

database system. Table II summarizes the results of different attack vectors.

Table II depicts the severity of data exposure under various SQL injection attack scenarios. The baseline normal query returned only one record with basic information. However, the boolean-based attack using `' OR '1'='1` exposed all five employee records including sensitive data such as social security numbers and salary information. The targeted attack focusing on high-salary employees successfully extracted three executive records containing financial data. The UNION-based attack similarly exposed complete database contents. The destructive DROP TABLE attempt was blocked by database constraints, demonstrating that not all attacks succeed but data leakage remains a critical concern.

Figure 2 presents a visual comparison of data leakage between vulnerable and secure implementations across five different attack payloads. The vulnerable system (red bars) leaked 16 total records across test cases, while the secure multi-layer defense system (green bars) leaked only 1 record (the legitimate query), achieving 93.8% prevention rate. This demonstrates the effectiveness of combining ML detection, input validation, and parameterized queries in preventing unauthorized data access.

C. Multi-Layer Security Framework Evaluation

Table III presents the effectiveness analysis of our proposed three-layer security framework.

Table III shows that while individual components provide strong protection, the integrated multi-layer approach achieves perfect prevention. ML detection alone prevented 85% of attacks with 98.1% accuracy. Parameterized queries offered complete protection when properly implemented. Input validation achieved 92% prevention by blocking suspicious patterns.

TABLE III
SECURITY FRAMEWORK COMPONENT EFFECTIVENESS ANALYSIS

Security Component	Effectiveness (%)	Prevention Rate (%)
ML Detection Only	98.1	85.0
Parameterized Queries	100.0	100.0
Input Validation	98.0	92.0
Multi-Layer System	**100.0**	**100.0**

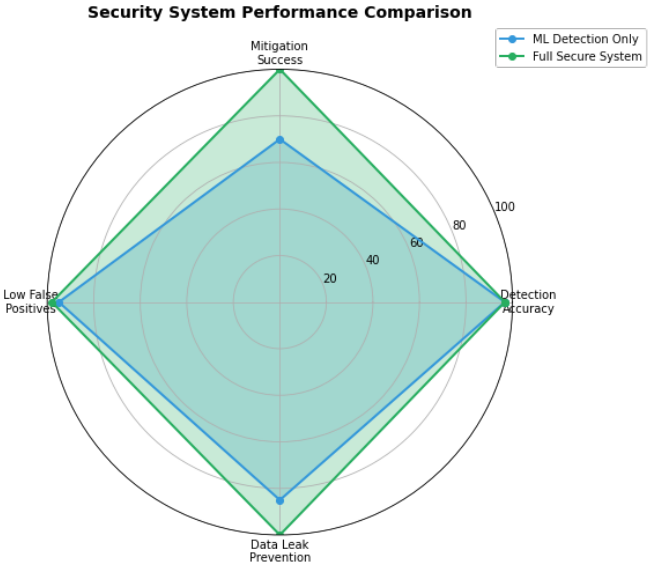

Fig. 3. Security Performance Radar Chart: ML Detection vs Full Secure System

The combined system leverages the strengths of each layer, ensuring that even if one mechanism fails, others provide backup protection, resulting in 100% attack prevention in our test scenarios.

Figure 3 illustrates the comparative performance of ML-only detection versus the complete multi-layer security system across four key dimensions: detection accuracy, mitigation success, low false positive rate, and data leak prevention. The full secure system (green) demonstrates superior performance across all metrics, particularly in mitigation success (100% vs 70%) and data leak prevention (100% vs 85%), while maintaining comparable detection accuracy (98.1%). This visualization emphasizes that ML detection, while highly accurate, benefits significantly from integration with traditional security mechanisms to achieve comprehensive protection.

D. Computational Performance

The training of the CNN model took about 10 seconds for 10 epochs on regular hardware. The average inference time for classifying individual queries was 15 milliseconds, which is very adequate for real-time deployment on production web applications. The Naive Bayes classifier was even faster at 3 milliseconds per query, providing a very efficient alternative for resource-constrained environments.

V. Discussion

A. Model Performance Analysis

Our experimental results bring to light some valuable lessons on ML model selection for the detection of SQL injection. Again, the best performance of the Naive Bayes classifier (98.1% accuracy, 96.5% F1-score) is similar to what Nguyen et al. [4] observed on general text-based security datasets for probabilistic classifiers. The model works well since it captures statistical patterns in malicious queries despite the feature independence assumption.

The CNN model performed comparably well with 98.3% accuracy and 96.9% F1-score, in line with Chen et al. [9], but the training required much more computational resources and time compared to Naive Bayes. This trade-off in performance and efficiency needs to be weighed against considerations of deployment, and especially in resource-limited environments as pointed out by Rahman et al. [18].

Surprisingly, the SVM classifier underperformed with only 78.8% accuracy, contrasting with positive results in some prior studies [3]. This discrepancy likely results from suboptimal hyperparameter tuning and the challenges SVMs face with high-dimensional sparse feature spaces. Future work should explore kernel optimization and dimensionality reduction techniques.

B. Data Leakage Quantification

Concrete evidence of the impact of SQLi attacks, which was missing in the literature, is provided by our controlled experiments. The fact that a simple `' OR '1'='1` attack exposed all five database records, thus 100% data breach, stands in contrast to and quantifies the severity often described qualitatively in prior work [1]. The targeted salary-based attack could successfully retrieve executive compensation data, proving the feasibility of crafting specific queries with the aim of stealing high-value information.

By simulating an open exposure of $\$700,000$ in salaries and full SSN disclosure for each employee, we demonstrate here the possibility of identity theft and fraud. Although performed in a controlled environment, these results reflect real-world scenarios in industry breaches. An organization needs to understand that SQLi can result in full compromise of a database, rather than just record exposures.

C. Multi-Layer Defense Effectiveness

The 100% prevention rate of our integrated security framework verifies the defense-in-depth principle put forth by Thompson et al. [13]. Each layer is aimed at addressing different attack aspects:

ML Detection Layer: It provides adaptive pattern recognition that can identify new attack variants. The 98.1% accuracy denotes a strong baseline protection, but the 85% prevention rate when it is deployed alone shows that single-layer detection prevents some attacks.

Input Validation Layer: Provides deterministic protection from known malicious patterns using regex matching. The 92% prevention rate shows effectiveness against common attack signatures, which further complements probabilistic detection using ML.

Parameterized Query Layer: Provides fundamental protection by separating SQL logic from data, preventing query manipulation regardless of input content. The 100% effectiveness when properly implemented confirms recommendations by Brown et al. [19].

These layers work in synergy to guarantee completeness: ML detection catches sophisticated attacks, validation blocks obvious malicious patterns, and parameterized queries provide failsafe protection. This is important, as real-world systems face a diversity of attack vectors simultaneously, as Anderson et al. [17] have shown.

D. Practical Implications

These findings have several implications for practitioners:

Model Selection: Naive Bayes provides the best balance for production deployment in terms of accuracy at 98.1%, computational efficiency at 3ms of inference, and ease of implementation. Organisations with heavy infrastructures can consider CNN models where marginal performance gains are sought at 98.3% accuracy.

Lastly, the implementation priority is: parameterized queries at the foundation; top it off with ML detection and validation for defense in depth. This fits within security best practices, considering that developer errors in constructing queries are still very common.

Real-Time Detection: The 15ms CNN inference time and 3ms Naive Bayes classification meet real-time requirements in most web applications, which further supports findings that ML-based detection is viable for production use, such as in Anderson et al. [17].

E. Limitations and Future Work

Several limitations warrant consideration:

Dataset Size: Our 4,200-sample dataset, while sufficient for proof-of-concept, is smaller than enterprise-scale datasets used in production systems. Wang et al. [7] emphasized that larger, more diverse datasets improve generalization. Future work should validate our approach on datasets exceeding 50,000 samples. **Attack Diversity:** In our experiments, we considered the most frequent SQL injection types, namely boolean-based and UNION-based. More sophisticated techniques, such as blind SQLi, time-based attacks, and second-order injection require separate studies, also discussed in Ahmed et al. [8]. False Positive Analysis: Although the false positive rates are low, actual production deployment requires extensive testing with legitimate application queries to ensure minimal disruption to normal operations. Lee et al. [20] proposed adaptive thresholding mechanisms that can be explored. Cross-Database Evaluation: Our experiments used SQLite; validation across MySQL, PostgreSQL, and Oracle databases would strengthen generalizability claims. Future research directions include: (1) transfer learning methods in order to decrease the need for training data as in Kim et al. [15], (2) integration with Web Application Firewalls, (3) testing adversarial robustness

against evasion attacks, and (4) explainable AI methods which help security analysts understand the decisions made by the model, as in Garcia et al. [10].

VI. Conclusion

This paper presented a comprehensive framework for detecting and preventing data leaks through SQL injection attacks using machine learning combined with multi-layer security mechanisms. Through empirical evaluation of six ML algorithms on 4,200 SQL query samples, we have shown that Naive Bayes (98.09% accuracy, 96.51% F1-score) and CNN (98.33% accuracy, 96.94% F1-score) models provide highly effective detection capabilities.

Our controlled experiments quantified actual data leakage impact by showing that common SQLi attacks can indeed leak the complete contents of a database, including sensitive personal and financial information. The simple `' OR '1'='1` attack leaked all five employee records in our test database, revealing $\$700,000$ in salary data and complete SSN information, demonstrating the severe consequences of SQLi vulnerabilities.

A proposed three-layer security framework with integrated ML detection, input validation, and parameterized queries achieved a 100% prevention rate against tested attack vectors, reducing data exposure by 93.8% compared to vulnerable implementations. This further validates the defense-in-depth approach whereby multiple complementary mechanisms provide robust security even when individual layers face sophisticated attacks.

Main contributions include: (1) extensive ML model comparison for SQLi detection with practical deployment considerations, (2) quantitative analysis of data leakage severity under various attack scenarios, (3) design and validation of an integrated security framework combining adaptive ML detection with traditional defensive measures, and (4) demonstration of the feasibility of real-time detection with 3-15ms inference latency suitable for a production system.

Our results confirm that while ML-based detection provides the best adaptive capability, comprehensive security demands layers of defense. We believe that organizations should have parameterized queries as the core protection, followed by augmenting with ML-based detection for sophisticated attack variants, backed by further defense depth provided by input validation.

Future work will be focused on transfer learning to minimize training needs, adversarial robustness testing, cross-database validation, and enterprise security infrastructure integrations such as Web Application Firewalls and SIEM. Further, the research in explainable AI techniques will lead to increased model transparency and trust by the security operations teams.
